Introduction

This guide provides best design practices for deploying the Cisco® Catalyst® Blade Switch 3130 Family for the Dell PowerEdge M1000e Blade Enclosure within the Cisco Data Center Networking Architecture. This guide describes the internal components of the blade server enclosure and Cisco Catalyst Blade Switch 3130 and explores different methods of deployment. It includes the following sections:

- The Dell PowerEdge M1000e Enclosure Overview
- The Cisco Catalyst Blade Switch 3130 Product Overview
- Design Goals
- Cisco Catalyst Blade Switch 3130 Features
- Network Topology Options
- Design and Implementation Details

The Dell PowerEdge M1000e Enclosure Overview

The Dell PowerEdge M1000e Enclosure represents the latest advancement in Blade Server and modular switch integration. Figure 1 below shows both a front and back side view of the cabinet. The M1000e enclosure provides redundant power, cooling, and management infrastructure for the blades and IO modules. It includes a highly available, passive midplane which connects the server blades to the power, management and IO infrastructure in the rear. The FlexIO architecture of the PowerEdge M1000e, of which Cisco Catalyst Blade Switches are a key part, enables unparalleled IO flexibility and bandwidth. The FlexIO architecture is based around six IO module bays which connect to the IO controllers on the server blades. The IO module bays were purposely designed to be large, providing sufficient space to implement features never before provided in blade based switches such as modular 10GbE uplinks and stacking functionality. The first two IO Bays must contain Ethernet modules as the onboard Ethernet controllers are routed to those bays. The additional four bays can be populated by additional Ethernet, Fibre Channel, and/or InfiniBand modules and connect to the option IO mezzanine cards on the blade servers.

Figure 1. Shows the Front and Back of the M1000e Enclosure

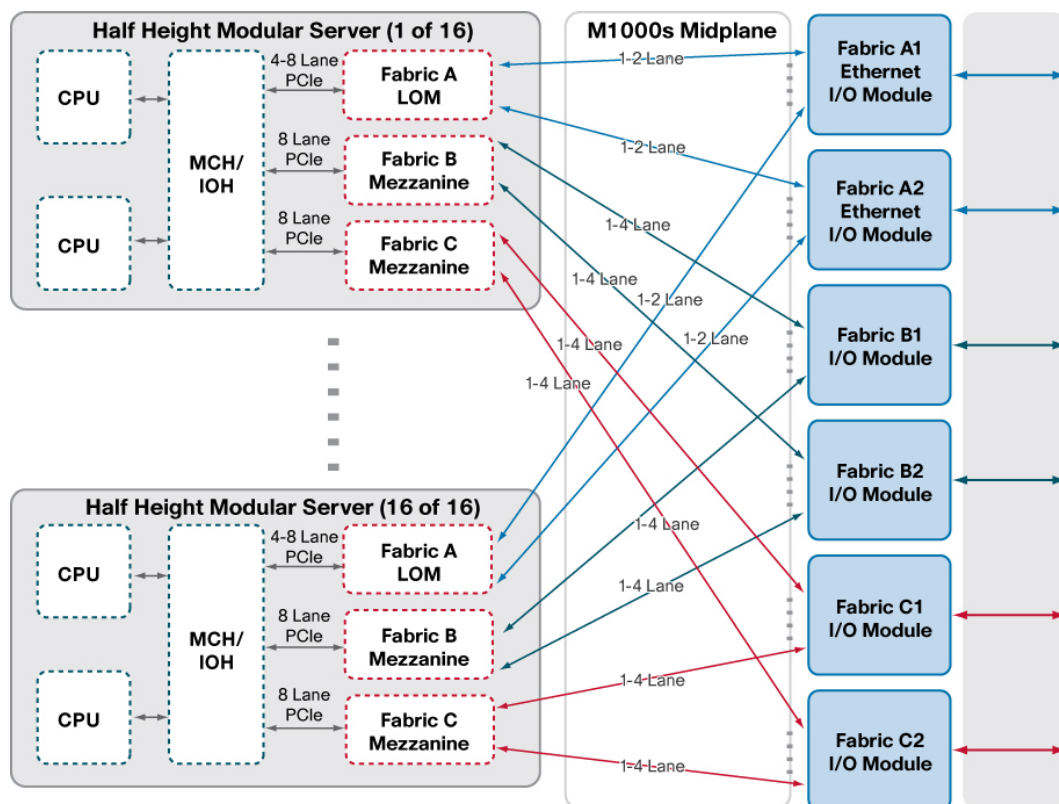

The enclosure's Midplane provides power and network connectivity to the blades. The base I/O module slots house a pair of Cisco Catalyst Blade Switch 3130s, which provide a highly available and multi-homed environment where each server blade is connected via Gigabit Ethernet attached to each Cisco Catalyst Blade Switch 3130. Two Cisco Catalyst Blade Switch 3130s within the blade

enclosure connect the blade server modules to external network devices such as aggregation layer switches.

Figure 2 shows the internal interconnections between the servers and the I/O modules.

Figure 2. Internal Server to Switch Routing

Fabric A is designed to support the LOM Ethernet interfaces. It is implemented as dual Broadcom 5708S Ethernet chips connected via separate 4x PCIe lanes to the CPU complex. Fabric B and Fabric C are supported via optional IO Mezzanine cards and are connected to the CPU complex by separate x8 PCIe lanes. Both fabrics support future 10 GE expansion. Each I/O module has both a serial and Ethernet connectivity to the CMC for out of band management.

The CMC GUI/CLI provides an interface for the customer to centrally configure static or dynamic IP address settings for the integrated switch modules in order to simplify deployment. Once these settings are defined, customers can access the web, telnet, or SSH interface of the CBS3130 via the management network to configure the switch.

The Cisco Catalyst Blade Switch 3130 Product Details

Figure 3. CBS3130 Family of Switches

Two products form the family: CBS3130G and CBS3130X. The CBS3130G provides four copper based Gigabit Ethernet ports and optionally four additional SFP based ports using the included Cisco TwinGig modules. The TwinGig ports support both fiber and copper based SFPs. The CBS3130X supports four copper based Gigabit Ethernet ports and two 10GE X2 based ports. The X2 based ports support SR, LRM, and CX4. Future support for LR and LX4 modules will be provided post FCS. The CBS3130X also ships with two TwinGig modules. All of these ports can be grouped to support the 802.3ad link aggregation protocol. Each blade server is connected to the backplane using the available Gigabit Ethernet network interface cards (NICs).

Server Port Configuration

A blade server is assigned a specific port on the blade switch. This is predetermined by the physical slot the blade server occupies in the enclosure. Table 1 correlates the server and switch ports

Table 1. Correlation of Server and Switch Ports

Cisco IOS Software CLI Identifier	Port Location in the Enclosure
GigabitEthernet x/0/1	Server Slot 1
GigabitEthernet x/0/2	Server Slot 2
GigabitEthernet x/0/3	Server Slot 3
GigabitEthernet x/0/4	Server Slot 4
GigabitEthernet x/0/5	Server Slot 5
GigabitEthernet x/0/6	Server Slot 6
GigabitEthernet x/0/7	Server Slot 7
GigabitEthernet x/0/8	Server Slot 8
GigabitEthernet x/0/9	Server Slot 9
GigabitEthernet x/0/10	Server Slot 10
GigabitEthernet x/0/11	Server Slot 11
GigabitEthernet x/0/12	Server Slot 12
GigabitEthernet x/0/13	Server Slot 13
GigabitEthernet x/0/14	Server Slot 14
GigabitEthernet x/0/15	Server Slot 15
GigabitEthernet x/0/16	Server Slot 16
GigabitEthernet x/0/17	Copper GE Uplink Port 1
GigabitEthernet x/0/18	Copper GE Uplink Port 2
GigabitEthernet x/0/19	Copper GE Uplink Port 3
GigabitEthernet x/0/20	Copper GE Uplink Port 4
GigabitEthernet x/0/21	SFP Port on TwinGig Module Port 1
GigabitEthernet x/0/22	SFP Port on TwinGig Module Port 2
GigabitEthernet x/0/23	SFP Port on TwinGig Module Port 3
GigabitEthernet x/0/24	SFP Port on TwinGig Module Port 4
TenGigabitEthernet x/0/1	10 GE Uplink Port (CBS3130X only)
TenGigabitEthernet x/0/2	10 GE Uplink Port (CBS3130X only)
Fa0	Management Interface

For interface names above the “x” indicates the member number. Interface FastEthernet0 (fa0) is connected internally to the CMC. Only the Fa0 interface on the master switch will be active when the switch is operating in Virtual Blade Switch (VBS) mode.

The Cisco Catalyst Blade Switch 3130 Product Overview

The Cisco Catalyst Blade Switch 3130 provides enhanced Layer 2 and Layer 3 services to Blade Servers. The CBS3130 ships standard with the IPBase software license, providing all the layer 2+ features Data Center customers are used to in the other Catalyst products. The CBS3130 family of switches now also supports basic routing functions: RIP and Static Routing, and EIGRP stub. The Cisco CBS3130 enhances basic Layer 2/3 switching by including Cisco proprietary protocols, access control lists (ACLs), and quality of service (QoS) based on Layer 3 information. With Simple Network Management Protocol (SNMP), command-line interface (CLI), or HTTP management options available and a robust set of Cisco IOS® Software switching features, the Cisco Catalyst Blade Switch 3130 naturally integrates into the data center environment. The following features highlight this capacity:

- Loop protection and rapid convergence with support for Per VLAN Spanning Tree Plus (PVST+), 802.1w, 802.1s, BDPU Guard, Loop Guard, PortFast, UplinkFast, and Unidirectional Link Detection (UDLD)
- Advanced management protocols, including Cisco Discovery Protocol, VLAN Trunking Protocol (VTP), and Dynamic Trunking Protocol (DTP)
- Port Aggregation Protocol (PAgP) and Link Aggregation Control Protocol (LACP) for link load balancing and high availability
- Support for authentication services, including RADIUS and TACACS+ client support
- Support for protection mechanisms, such as limiting the number of MAC addresses allowed or shutting down the port in response to security violations

The CBS3130 brings one additional feature not found in other Ethernet Blade switches: The ability to form a Virtual Blade Switch. By combining the Blade switches together via the high speed interconnect cables, the CBS3130 can emulate a redundant Top of the Rack (ToR) solution.

A Virtual Blade Switch offers the following features not present in other Blade Switches:

- A single point of management for the entire Rack of up to 8 Ethernet Switches.
 - One IP address for Management
 - Single upgrade for the entire rack of VBS enabled switches. The user only upgrades the master switch and the master upgrades the members.
 - Single configuration file for entire rack- The Ring has one master switch which provides the management functions. In case of failure of the master, each member switch is capable of taking over the master functions. Additional switches can be added to the configuration without taking down the existing members. If a member switch fails, the high speed ring connections will loop back around the failed device.
 - Single STP instance for L2 networks and a single Router domain for L3 networks
- Consolidation of uplink ports- in a VBS environment, there is no longer a requirement to uplink from each individual switch into the aggregation layer.

Figure 4 shows a diagram of a Virtual Blade Switch configuration. In this configuration, two member switches have a 10GE Ethernet connection to the aggregation layer. These two cables can be EtherChannelled together to form a 20GE pipe. The number of uplinks is dependent on traffic flow; typically two to four are used for the entire rack. Placing the uplinks on different member switches and in different enclosures helps insure maximum resiliency against switch or enclosure failure. The maximum raw capacity of the ring is 64 Gbps; actual throughput depends on traffic patterns and traffic type.

Figure 4. Virtual Blade Switch Configuration

Data Center Network Architecture

The architecture of the data center infrastructure must address the requirements necessary to create a highly available, scalable, and secure network. This section describes the basic architecture necessary to meet these goals.

It is a synopsis of the Cisco Data Center Network Architecture and includes the following topics:

- Data Center Network Components
- Aggregation Layer
- Access Layer
- High Availability
- BladeSystem in the Data Center Architecture

For details about this architecture, refer to the guide at:

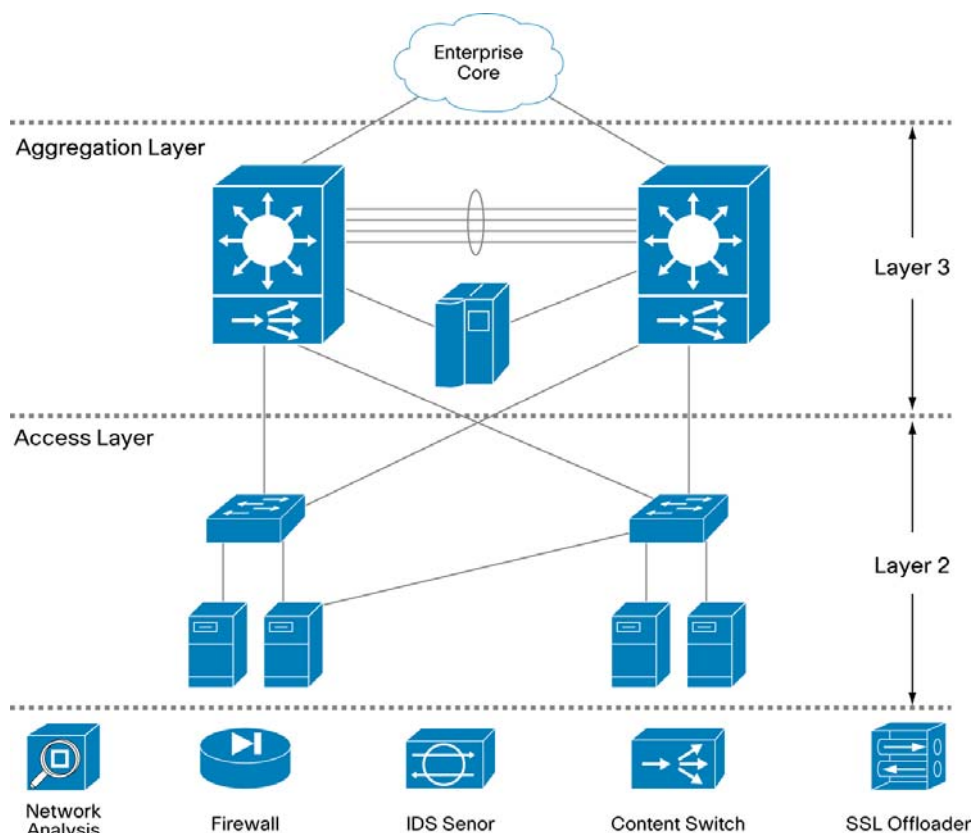

http://www.cisco.com/en/US/solutions/ns340/ns517/ns224/ns304/net_design_guidance0900aecd800e4d2e.pdf

Data Center Network Components

The terms front-end network and back-end network define the devices that comprise the infrastructure of the data center and their general role. The front-end network is the IP routing and switching environment. It provides client-to-server, server-to-server, and server-to-storage network connectivity. The back-end network supports the SAN fabric and connectivity between servers and other storage devices such as storage arrays and tape drives.

The front-end network contains two distinct functional areas called the aggregation and access layers. Figure 5 depicts the network and the services available at each layer.

Figure 5. Data Center Front-End Network

Aggregation Layer

The aggregation layer is a point of convergence for network traffic that provides connectivity between server farms and the rest of the enterprise. The aggregation layer supports Layer 2 and Layer 3 functionality and presents an ideal location for deploying centralized application, security, and management services. These data center services are shared across the access layer server farms and provide an efficient, scalable, predictable, and deterministic behavior common to server farm needs.

The aggregation layer provides a comprehensive set of features for the data center. The features are supported by the following devices:

- Multilayer aggregation switches
- Load-balancing devices
- Firewalls
- Intrusion detection systems
- Content engines
- Secure Sockets Layer (SSL) off loaders
- Network analysis devices

Access Layer

The primary role of the access layer is to provide the server farms with port density. In addition, it must be a flexible, efficient, and predictable environment supporting client-to-server and server-to-server traffic. A Layer 2 domain meets these requirements by providing the following:

- Adjacency between servers and service devices
- A deterministic, fast converging, loop-free topology

Layer 2 adjacency, in the server farms, allows for the deployment of servers or clusters that require the exchange of information done at Layer 2 only. It also readily supports access to network services in the aggregation layer such as load balancers and firewalls. This enables an efficient use of shared, centralized network services by the server farms. In contrast, if services are deployed at each access switch, the benefit of those services is limited to the servers directly attached to the switch. It is easier to insert new servers into the access layer when the aggregation layer is responsible for data center services, and the Layer 2 environment provides the flexibility to scale the number of ports. This is another benefit provided in a Layer 2 access layer.

The access layer must provide a deterministic environment to help ensure a stable Layer 2 domain. A predictable access layer allows the spanning tree to converge and recover quickly during failover and fallback scenarios.

The Catalyst Blade Switch 3130 provides additional L3 routing capabilities for those customers who require L3 on the edge. The included IPBase software license includes RIP, Static Routing, and EIGRP Stub. The EIGRP Stub features allow the CBS3130 to act as an edge router in an EIGRP network. In addition, key security features such as Dynamic Arp Inspection (DAI) and IP Source Guard are provided in the IPBase software.

Optional licenses for IP Services and Advanced IP Services are available. IP Services license adds additional routing protocols such as OSPF, BGP, and multicast routing. The Advanced IP Services license includes IPv6 routing and associated protocols. IPv6 Management is included as a standard in all licenses.

Design Goals

This section describes the design goals when deploying blade servers and the functionality supported by the Cisco Catalyst Blade Switch 3130 in data centers. It includes the following topics:

- High Availability
- Scalability
- Management

High Availability

High availability in the data center is a goal that must be achieved systematically. A highly available environment is attainable by addressing each layer of the data center and each of the devices that comprise that particular data center layer. Network and software features help achieve high availability, as well as physical redundancy of links and devices.

The aggregation and access layers use redundant devices and links to help ensure there is no single point of failure. The Layer 2 and/or Layer 3 features supported by these switches also create a highly available infrastructure. Spanning Tree Protocol support on both the aggregation and access switches creates a deterministic topology that converges quickly. Logical redundancy or

fault tolerance may be achieved with Layer 3 technologies such as Hot Standby Router Protocol (HSRP) or Virtual Router Redundancy Protocol (VRRP). These protocols allow the gateways for servers or clients to be virtualized across the physical routing devices in the network. This virtualization mitigates the effect of a routing device failure on the availability of data center services. Load-balancing services deployed in the aggregation layer allow the network to monitor server health and application availability. These devices and features combined produce a more resilient application environment.

Dual-homing a server in relation to separate access layer switches is another method to achieve a higher level of availability in the data center. NIC teaming removes the possibility of a single NIC failure isolating the server. It requires the server to have two separate NICs that support teaming software. Typically, teaming software detects failures over an external network probe between members of the team or by monitoring the local status of each NIC in the team. The combination of dual-homed servers and a network load balancer provides an even greater level of availability for the server and the applications it supports.

Data centers are the repository of critical business applications that support the continual operation of an enterprise. These applications must be accessible throughout the working day during peak times, and some on a 24-hour basis. The infrastructure of the data center, network devices, and servers must address these diverse requirements. The network infrastructure provides device and link redundancy combined with a deterministic topology design to achieve application availability requirements. Servers are typically configured with multiple NICs and dual-homed to the access layer switches to provide backup connectivity to the business application.

High availability is an important design consideration in the data center. The Cisco Catalyst Blade Switch 3130 has a number of features and characteristics that contribute to a reliable, highly available network.

High Availability for the Blade Server Switching Infrastructure

High availability between the Cisco Catalyst Blade Switch 3130s in the blade server enclosure and the aggregation layer switches requires link redundancy. Each Cisco Catalyst Blade Switch 3130 offers multiple ports for uplink connectivity to the external network, which allows for redundant paths using links to each aggregation layer switch for more redundancy. However, this introduces the possibility of Layer 2 loops; therefore, a mechanism is required to manage the physical topology. The implementation of RSTP helps ensure a fast converging, predictable Layer 2 domain between the aggregation layer and access switches (the Cisco Catalyst Blade Switch 3130s) when redundant paths are present. For those customers who want to implement the Access layer without Spanning Tree, the CBS3130 supports FlexLinks. FlexLinks associates a “back up” interface with each forwarding interface. There, the customer can maintain a redundant topology without the need for spanning tree.

A recommended design is a triangle topology (as shown in Figure 5 earlier), which delivers a highly available environment through redundant links and a spanning tree. It allows for multiple switch or link failures without compromising the availability of the data center applications.

The access layer uplink EtherChannels support the publicly available subnets in the data center and traffic between servers. The server-to-server traffic that uses these uplinks is logically segmented through VLANs and may use network services available in the aggregation layer. This path provides intra-enclosure connectivity between the servers for VLANs defined locally on the blade enclosure switches. Clustering applications that require Layer 2 communication may use this

traffic path, as well as mirrored traffic. Each of these port channels is composed of at least two Gigabit Ethernet or two 10GE ports.

RPVST+ is recommended as the method for controlling the Layer 2 domain because of its predictable behavior and fast convergence. A meshed topology combined with RPVST+ allows only one active link from each blade switch to the root of the spanning tree domain. This design creates a highly available server farm through controlled traffic paths and the rapid convergence of the spanning tree. The details of the recommended design are discussed in a later section.

High Availability for the Blade Servers

Blade enclosures provide high availability to blade servers by multihoming each server to the Cisco Catalyst Blade Switch 3130s. The two Cisco Catalyst Blade Switch 3130s housed in the interconnect bays are connected to the blade server over the backplane. Six backplane Gigabit Ethernet connections are available to every blade server: two for the LAN on Motherboard (LOMs) and four via mezzanine cards.

Multihoming the server blades allows the use of a NIC teaming driver, which provides another high-availability mechanism to fail over and load balance at the server level. Broadcom uses basically two modes of teaming are supported:

- Smart Load Balancing (SLB)
- Link Aggregation (with IEEE 802.1ad LACP)

Smart Load Balancing is done based on L3 addresses. On a per flow basis, the Broadcom adapter will assign the associated MAC address for the particular NIC the traffic will use. Load Balancing is not done on a packet by packet basis.

LACP based teaming extends the functionality by allowing the team to receive load-balanced traffic from the network. This requires that the switch can load balance the traffic across the ports connected to the server NIC team. LACP based load balancing is done on the L2 address. The team of NICs looks like a larger single NIC to the switch, much like an EtherChannel looks between switches. Redundancy is built into the protocol. The Cisco Catalyst Blade Switch 3130 supports the IEEE 802.3ad standard and Gigabit port channels. Servers can now operate in Active/Active configurations. This means that each server team can provide 2 Gigabit of Ethernet Connectivity to the Switching fabric. Failover mechanisms are automatically built into the LACP protocol. The pair of CBS3130s must be in the same ring for the server to support LACP connections. In other words, the server must see the same switch on both interfaces. Otherwise, the user most likely will use the SLB mode.

For more information on NIC teaming, please visit:

http://support.dell.com/support/edocs/network/r35278/broadcom%20nic%20teaming_1.1_final.doc

Scalability

The capability of the data center to adapt to increased demands without compromising its availability is a crucial design consideration. The aggregation layer infrastructure and the services it provides must accommodate future growth in the number of servers or subnets it supports.

When deploying blade servers in the data center there are two primary factors to consider:

- Number of physical ports in the aggregation and access layers
- Number of slots in the aggregation layer switches

Aggregation Layer Switch Physical Port Count

The introduction of blade systems into the data center requires greater port density at the aggregation layer. Blade systems, deployed with internal switches, provide their own access layer. The cabling and maximum number of servers per enclosure is predetermined. Scaling the aggregation-layer ports to accommodate the blade system uplinks is an area that requires attention.

It is important to remember that aggregation switches provide data center services such as load balancing, security, and network analysis that may require dedicated ports for appliances or slots for integrated services. This directly affects the number of ports available for access-layer connectivity.

Aggregation Layer Switch Slot Count

The data center infrastructure must be flexible enough to allow growth in both server capacity and service performance. Connecting a blade system directly into the aggregation layer places more significance on the number of slots available to accommodate blade system uplinks and integrated services.

Traditionally, the access layer provides the port density necessary to allow the physical growth of server farms. Modular access-layer switches offer connectivity to densely packed server farms over a few uplinks. The aggregation-layer switches support a limited number of uplinks from the access layer. With this model, the number of servers supported per uplink is high.

Blade systems use more aggregation-layer resources per server than this traditional deployment model. Each uplink from a blade enclosure provides connectivity to a maximum of 16 servers. The aggregation layer must be flexible enough to manage the increased demand for ports and slots in this blade server system environment.

To scale the server farm, use an aggregation-layer switch that provides an ample number of slots for line cards and/or service module expansion.

In addition, consider using the following two options (which are not mutually exclusive):

- Deploying service switches in the aggregation layer (as depicted in Figure 8)
- Using a data center core to accommodate multiple aggregation-layer modules

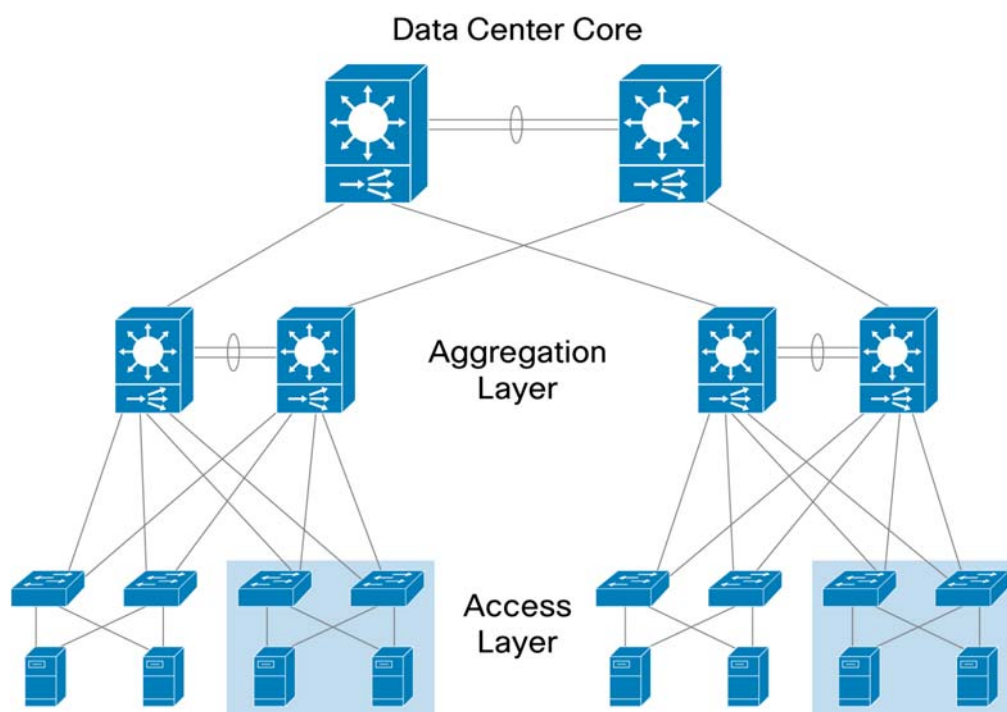

Service switches are deployed in the aggregation layer to host integrated data center services such as load balancing, intrusion detection, and network analysis. Relocating these services to a separate switch frees ports and slots in the aggregation-layer switches. This design allows the aggregation switches to commit more slots and, ultimately, more ports to the Layer 2 connectivity of the server farms.

The data center core is a mechanism to replicate and horizontally scale the data center environment. In the recommended design the aggregation and access layers are regarded as a module that can be duplicated to extend the enterprise. Each data center module provides its own network services locally in the aggregation switches. This approach allows the network administrator to determine the limits of each data center module and replicate as necessary.

Figure 6 depicts the data center design. The aggregation switches for each data center module are Layer 3 attached to the core. In addition, the aggregation switches house the service modules required to support the server farms. The aggregation layer provides the connectivity layer for the

various Access Layer switches. In a typical Data Center network, this layer will have connections from Blade and non-Blade switches, providing connectivity all the servers in the network.

Figure 6. Data Center Design

Management

The Cisco Catalyst Blade Switch 3130 is accessible for management and configuration by any of the following traffic paths:

- Out-of-band management
- In-band management
- Serial console port

These traffic paths provide three different management options for network administration and support different user and application interfaces to the Cisco Catalyst Blade Switch 3130. The remote management of the blade servers within the blade enclosure is critical to an efficient and scalable data center. The various Blade Server vendors offer connectivity options provided using the enclosure to the blade servers are also discussed. See the particular Appendix for your enclosure type.

Out-of-Band Management

Out-of-band management is the practice of dedicating an interface on the managed device for carrying management traffic. It is also the recommended management method for blade systems. Out-of-band management isolates the management and data traffic and provides a more secure environment.

The Cisco Catalyst Blade Switch 3130 contains an additional Fast Ethernet port, which connects to the Dell Chassis Management Controller (CMC), providing out-of-band management using the CMC interface (GUI or CLI). The user may also use this path to access the CLI functions of the switch, transfer SNMP information, and upload software images and configuration files. This path is

totally independent of the switch fabric. This Fast Ethernet port (Fa0) defaults to a DHCP client from a DHCP server external on the network attached to the Enclosure. The user can also set a static IP address for the Fast Ethernet port via the CMC interface or the serial port.

When the CBS3130 is operated as a standalone switch, it operates in the same manner as the CBS3030. However, when a collection of CBS3130s are connected via the high speed ring ports, the switches operate as a single entity. In this mode, only the Fa0 port on the Master switch is active. The Fa0 ports on the member switches are temporarily disabled. If the ring breaks, the two separate new rings will have two new Master switches, and therefore, the Fa0 ports of those two Master switches will both be active. For more information on this, see the Virtual Blade Switch Operations Section in this document.

In-Band Management

In-band management uses logical isolation to separate management traffic from data traffic. VLANs segregate the two traffic types that are sharing the bandwidth of the uplink ports. This practice is common where applications running on the servers must be managed along with the network infrastructure devices.

In-band management traffic uses the uplink trunk ports located on the Cisco Catalyst Blade Switch 3130s for management. It is recommended that you do not put the user ports in the same VLAN as the management VLAN.

The Cisco Catalyst Blade Switch 3130 supports multiple switched virtual interfaces (SVIs) to be active at the same time; however, the Cisco Catalyst Blade Switch 3130 does not perform any routing functions between SVIs. By default, the SVI is created as VLAN 1 and enabled during the setup phase of the installation. The VLAN is often referred to as the “management VLAN.” Cisco Systems® recommends that the user change the management VLAN to something other than VLAN 1. Therefore, it is important to create an SVI with another VLAN and allow this VLAN on the external front panel ports. In addition, you can manage the switch using the Fa0 port using the Onboard Administrator on the rear of the enclosure.

For best practices in selecting the management VLAN, please visit:

http://www.cisco.com/en/US/products/hw/switches/ps700/products_white_paper09186a00801b49a4.shtml

Serial Console Port

The front panel of the Cisco Catalyst Blade Switch 3130 has a serial port that can be used to manage the switch through the CLI. In addition, the CMC controls an internal serial port that can be directed to the CBS3130 by using the “connect switch-x” command in the CMC CLI. The CLI can be accessed by connecting directly to the external console port, by connecting via the RACADM command in the CMC, or remotely by using terminal servers and IP connectivity protocols such as telnet or SSH. Even when the switches are connected via the high speed ring ports, all console ports are active. However, traffic is routed to the CPU on the Master switch. Therefore, every console port acts the same. If the user is connecting the switches to a console server, then the user should hook up at least two console cables per Virtual Blade Switch, to insure connectivity in case of switch outage.

Management Options

The Cisco Catalyst Blade Switch 3130 switch is manageable through the following methods:

- Cisco IOS Software CLI (via console, telnet, or SSH)
- HTTP-based Device Manager GUI
- Cisco Device Manager (CNA, version 5.3 and greater)
- SNMP-based management applications

The embedded device manager on the Cisco Catalyst Blade Switch 3130 provides a GUI to configure and monitor the switch through a Web browser. This requires using either in-band or out-of-band management and enabling the HTTP/HTTPS server on the switch. The HTTP server and SSL are enabled by default.

SNMP-compatible management utilities are supported through a comprehensive set of MIB extensions and through four remote monitoring (RMON) groups. CiscoWorks 2000, IBM Director and HP OpenView are two such management applications. SNMP Versions 1, 2, and 3 are available on the switch (Cisco IOS Software crypto image).

The CLI delivers the standard Cisco IOS Software interface over telnet or the console port. The use of SSH for CLI access is recommended.

Note: For more information about the embedded device manager, refer to the online help on the switch CLI.

Design and Implementation Details

This section includes the following topics:

- Network Management Recommendations
- Network Topologies Using Cisco Catalyst Blade Switch 3130
- Configuration Details

Network Management Recommendations

An out-of-band (OOB) network is recommended for managing the Cisco Catalyst Blade Switch 3130. OOB management provides an isolated environment for monitoring and configuring the switch. Isolation is achieved by deploying a physically separate management network or by logically separating the traffic with management VLANs.

The Cisco Catalyst Blade Switch 3130 has four external Gigabit Ethernet ports; any of them may be used to support network monitoring devices and network management traffic. The operator may choose to use the Fa0 port for OOB management. By using secure protocols, such as SSH or HTTPS, the network maintains the integrity of communications between the switch and the management station. The console port positioned at the front of the Cisco Catalyst Blade Switch 3130 is another option for connectivity to the OOB network.

If the CBS3130s are connected together via the VBS connectors, then placement of the management monitoring devices may impact traffic flow. If the user is sniffing local ports, then traffic does not traverse the ring. However, even if the user is using SPAN to sniff traffic from ports not on the local member switch, that traffic must travel on the high speed ring. This may reduce the ring capacity and cause or add to an oversubscription environment.

Cisco Catalyst Blade Switch 3130 Features

This section highlights information about the protocols and features provided by the Cisco Catalyst Blade Switch 3130 that help integrate blade server enclosures into the Cisco Data Center Network Architecture. This section includes the following topics:

- VBS Ring Architecture
- Spanning Tree
- FlexLink
- Downstream EtherChannel to servers
- Upstream Cross Switch EtherChannel
- Traffic Monitoring
- Link Aggregation Protocols

VBS Ring Architecture

Each CBS3130 switch has two connectors that allow it to become a member of a Virtual Blade Switch (VBS). The switches are connected on a Ring. The ring is made up of two counter rotating uni-directional traffic lanes. Each lane has a raw capacity of 16 Gbps. A member on the ring can transmit and receive in both directions, so the ring capacity has a raw data rate of 64 Gbps.

The ring access is done on a token passing and credit assignment basis. When each member needs to transmit data, it waits for a token to arrive from either direction. Once it receives the token, it is allowed to transmit a block of traffic. If it exceeds its credits, it must wait for the token to return and then transfer again. Each time the member request credits, it may get them from either direction.

The maximum number of physical switches per VBS is 9. Due to the fact that most customers use them in pairs, the normal limit is 8. This works out to approximately one VBS per rack, assuming you have four enclosures per rack. A single VBS then services between 56 and 64 servers. A VBS also eliminates up to 128 Ethernet cables.

The primary difference between VBS and standalone operation is from the server side. In a standalone configuration, the CBS3130 operates much like the CBS30x0 series. Each server sees two separate switches. In the VBS configuration, the server only sees one switch for both NICs. Therefore, in the VBS configuration, the server can enable Active-Active NIC teaming.

A VBS seen from the upstream aggregation switch is no different than a standalone switch. Therefore the decision to select the network topology configuration for connecting to the aggregation switches is the same for both. The options for network topologies will be discussed later.

Additional configuration is when all the left switches in a rack are placed into one VBS configuration and all the right switches are in another. In this case, the upstream interfaces from each VBS follow the above model. However, the downstream side facing the servers looks like the standalone model. The user may choose this configuration, if he requires two completely isolated network fabrics.

Ring Design and Capacity

As mentioned before, each member switch has two ring connections. Each connection is 16 Gbps bidirectional. Basically, there are two counter rotating rings. The amount of raw traffic an individual switch can process is 64 Gbps (32 Gbps transmit and 32 Gbps receive).

Much like Ethernet, the user available traffic on the ring, is less. Whereas, Ethernet implements a 20 byte Inter Packet Gap (IPG), the ring does not. However, the switch fabric chips put a 24 byte header on each data frame to signify the source and destination switch for the packet. Each Unicast transmitted packet is removed from the ring by the destination switch and the destination switch sends a 16 byte ACK back to the source switch. Ring capacity for Unicast traffic is ~ 48 Gbps.

For Multicast and Broadcast traffic, the packet travels all the way around the ring and is stripped off by the sending switch when it returns. No ACKs are sent. In this case, the ring capacity drops to 26-28 Gbps.

Since normal traffic mix is a combination of Unicast, Broadcast, and Multicast, the actual capacity may vary anywhere between 26 and 48 Gbps, and in some rare cases may actually exceed the 48 Gbps rate.

Spanning Tree

The Cisco Catalyst Blade Switch 3130 supports different versions of the Spanning Tree Protocol and associated features, including the following:

- Rapid Spanning Tree (RSTP), based on 802.1w
- Multiple Spanning Tree (MST), based on 802.1s (and includes 802.1w support)
- Per VLAN Spanning Tree Plus (PVST+)
- Rapid Per VLAN Spanning Tree Plus (RPVST+)
- Loop Guard
- UDLD
- BPDU Guard
- PortFast
- UplinkFast (Cisco proprietary enhancement for 802.1d deployments)
- BackboneFast (Cisco proprietary enhancement for 802.1d deployments)

The 802.1w protocol is the standard for rapid spanning tree convergence, while 802.1s is the standard for multiple spanning tree instances. Support for these protocols is essential in a server farm environment for allowing rapid Layer 2 convergence after a failure occurs in the primary path. The primary benefits of 802.1w include the following:

- The spanning tree topology converges quickly after a switch or link failure.
- Convergence is accelerated by a handshake, known as the proposal agreement mechanism.

Note: PortFast, BackboneFast, or UplinkFast apply only to PVST+ based networks.

In terms of convergence, Spanning Tree Protocol algorithms based on 802.1w are much faster than the traditional Spanning Tree Protocol 802.1d algorithms. The proposal agreement

mechanism allows the Cisco Catalyst Blade Switch 3130 to decide new port roles by exchanging proposals with its neighbors.

With 802.1w, as with other versions of the Spanning Tree Protocol, bridge protocol data units (BPDUs) are by default sent every 2 seconds (called the hello time). If three BPDUs are missed, Spanning Tree Protocol recalculates the topology, which takes less than 1 second for 802.1w.

Since the data center is made of point-to-point links, the only failures are physical failures of the networking devices or links. 802.1w is able to actively confirm that a port can safely transition to forwarding without relying on any timer configuration. This means that the actual convergence time is less than 1 second.

A scenario where BPDUs are lost may be caused by unidirectional links, which can cause Layer 2 loops. To prevent this problem, you can use Loop Guard and UDLD. Loop Guard prevents a port from forwarding as a result of missed BPDUs, which might cause a Layer 2 loop that could bring down the network.

UDLD allows devices to monitor the physical configuration of fiber optic or copper Ethernet cables and detect when a unidirectional link exists. When a unidirectional link is detected, UDLD shuts down the affected port and generates an alert. BPDU Guard prevents a port from being active in a spanning tree topology as a result of an attack or a misconfigured device connected to the switch port. The port that sees unexpected BPDUs is automatically disabled and must then be manually enabled. This gives the network administrator full control over port and switch behavior.

The Cisco Catalyst Blade Switch 3130 supports Per VLAN Spanning Tree (PVST) and a maximum of 128 spanning tree instances. RPVST+ is a combination of Cisco PVST Plus (PVST+) and RSTP. RPVST+ provides the flexibility of one spanning tree instance per VLAN and the fast convergence benefits of 802.1w. MST allows the switch to map several VLANs to one spanning tree instance, reducing the total number of spanning tree topologies the switch processor must manage. A maximum of 16 MST instances is supported. In addition, MST uses 802.1w for rapid convergence. MST and RPVST+ create a more predictable and resilient spanning tree topology, while providing downward compatibility for integration with devices that use 802.1d and PVST+ protocols.

Figure 8 illustrates an example for Spanning Tree Protocol when using two switches in the crossover configuration. Each blade switch is dual homed to each aggregation switch via a 2-port EtherChannel®. In this figure the blocked links are indicated in red. In this example, only four of the eight uplinks from each blade switch are in use. The network designer can make those EtherChannel uplinks more robust (up to four ports each), or use them to connect other devices such as intrusion detection systems (IDS) or standalone servers.

Figure 7. Spanning Tree Example with the Cisco Catalyst Blade Switch 3130s

Note: The 802.1w protocol is enabled by default when running spanning tree in RPVST+ or MST mode on the Cisco Catalyst Blade Switch 3130. The Cisco Catalyst Blade Switch 3130 enables PVST+ for VLAN 1 by default.

Spanning tree uses the path cost value to determine the shortest distance to the root bridge. The port path cost value represents the media speed of the link and is configurable on a per-interface basis, including Cisco EtherChannel interfaces. The longer path cost better reflects changes in the speed of channels and allows Spanning Tree Protocol to optimize the network in the presence of loops.

Note: The Cisco Catalyst Blade Switch 3130 supports IEEE 802.1t, which allows for spanning tree calculations based on a 32-bit path cost value instead of the default 16 bits. For more information about the standards supported by the Cisco Catalyst Blade Switch 3130, refer to the “Cisco Catalyst Blade Switch 3130 Overview” document.

For more information regarding spanning tree and Layer 2 design in the data center, refer to: http://www.cisco.com/en/US/solutions/ns340/ns517/ns224/ns304/net_design_guidance0900aecd800e4d2e.pdf

FlexLinks

An alternative to STP is FlexLinks. FlexLinks gives you the ability to make active-standby pairs and provide redundancy without needing to use STP. FlexLinks can be implemented on a VLAN by VLAN basis much like STP. For the example in Figure 7, the top EtherChannel can be active for one VLAN and be standby for another. This allows both uplinks to be active at the same time and share the network load.

Traffic Monitoring

The Cisco Catalyst Blade Switch 3130 supports the following traffic monitoring features, which are useful for monitoring blade enclosure traffic in data center environments:

- Switched Port Analyzer (SPAN)
- Remote SPAN (RSPAN)

SPAN mirrors traffic transmitted or received on source ports or source VLANs to another local switch port. This traffic can be analyzed by connecting a switch or RMON probe to the destination port of the mirrored traffic. Only traffic that enters or leaves source ports or source VLANs can be monitored using SPAN.

RSPAN enables remote monitoring of multiple switches across your network. The traffic for each RSPAN session is carried over a user-specified VLAN that is dedicated to that RSPAN session for all participating switches. The SPAN traffic from the source ports or source VLANs is copied to the RSPAN VLAN. This mirrored traffic is then forwarded over trunk ports to any destination session that is monitoring the RSPAN VLAN.

Link Aggregation Protocols

Fast EtherChannel interfaces and Gigabit EtherChannel interfaces are logically bundled and provide link redundancy and scalable bandwidth between network devices. The Port Aggregation Protocol (PAgP) and Link Aggregation Control Protocol (LACP) help automatically create these channels by exchanging packets between Ethernet interfaces and negotiating a logical connection. PAgP is a Cisco proprietary protocol that can be run only on Cisco switches or on switches manufactured by vendors that are licensed to support PAgP. LACP is a standard protocol that allows Cisco switches to manage Ethernet channels between any switches that conform to the 802.3ad protocol. Because the Cisco Catalyst Blade Switch 3130 supports both protocols, you can use either 802.3ad or PAgP to form port channels between Cisco switches.

When using either of these protocols, a switch learns the identity of partners capable of supporting either PAgP or LACP and identifies the capabilities of each interface. The switch dynamically groups similarly configured interfaces into a single logical link, called a channel or aggregate port. The interface grouping is based on hardware, administrative, and port parameter attributes. For example, PAgP groups interfaces with the same speed, duplex mode, native VLAN, VLAN range, trunking status, and trunking type. After grouping the links into a port channel, PAgP adds the group to the spanning tree as a single switch port.

Network Topologies Using the Cisco Catalyst Blade Switch 3130

The network designs emphasize high availability in the data center by eliminating any single point of failure and by providing deterministic traffic patterns and predictable behavior during times of network convergence. The configuration example included uses a pair of Cisco Catalyst 6513 Switches as the aggregation-layer platform. This Layer 2/Layer 3 switching platform supports the slot density and integrated network services required by data centers deploying blade systems. A generic Blade Server cabinet and at least two Cisco Catalyst Blade Switch 3130s composes the Layer 2 access layer.

Cross Over Design (AKA “V” or Triangle configuration)

Typical deployment in the data center uses the classic triangle topology. There is no single point of failure in this deployment model. It does not matter if the Catalyst Blade Switch 3130s are operating in the standalone environment or in VBS mode. At least two switches are dual-homed to the

aggregation layer, providing link redundancy. Spanning Tree Protocol manages the physical loops created by the uplinks between the aggregation and access switches, assuring a predictable and fast converging topology.

RPVST+ fulfills the high-availability requirements of this design and is the recommended mode of spanning tree operation. RPVST+ provides fast convergence (less than 1 second) in device or uplink failure scenarios. In addition, RPVST+ offers enhanced Layer 2 features for the access layer with integrated capabilities equivalent to PortFast, UplinkFast, and BackboneFast.

If the user wants to eliminate STP from the network, the Cross over Design can be implemented using FlexLinks.

The connection between blade switches (in VBS mode) supports local traffic limited to the local rack: for example, clustering applications or management traffic such as remotely mirrored (RSPAN) traffic. Local traffic does not need to go up to 6513s and back. It can stay within the local ring. Of course, if the CBS3130s switches are running in standalone mode, they can not take advantage of this.

The server NICs support the logical separation of VLANs by trunking. This allows each NIC to accommodate the public and the private VLANs on the Cisco Catalyst Blade Switch 3130s. In addition, servers are dual-homed to each of the two Cisco Catalyst Blade Switch 3130s in the enclosure. This structural design can also allow for the physical separation of public and private VLANs between two NICs homed to the same Cisco Catalyst Blade Switch 3130.

In VBS mode, the cross-over topology provides a high level of availability to the blade servers. If all the uplinks from any blade switch in the ring to any of the aggregation switches are unavailable, the server NICs homed to that Cisco Catalyst Blade Switch 3130 will route traffic onto the ring to another member switch which has an upstream connection. The blade servers are unaware of the disconnection between the access-layer switches (Cisco Catalyst Blade Switch 3130s) and the aggregation-layer switches and continue to forward traffic.

In the standalone mode, this is not the case. Since there is no ring connection, server NICs could end up black holing traffic to a switch that has no uplinks. To address this breakdown in network connectivity, use the following methods:

- Use the NIC teaming features of the blade servers
- Deploy Layer 2 trunk failover feature in the Cisco Catalyst Blade Switch 3130s

In addition, the NIC teaming features of the blade servers provide redundancy at the network adapter level. Stagger the preferred primary NICs between the two Cisco switches in the enclosure to increase server availability. Assigning the primary NIC is a straightforward process. The NIC teaming software provides a GUI or a small configuration file, depending on the operating system, to construct the team.

Non-Loop Design (AKA “U” or Square configuration)

When the CBS3130 switches are used in standalone environment, a Non-Loop design can be deployed. The Non-Loop topology follows the same design guide lines as for the CBS30x0 products. Basically all the uplinks from one blade switch run to one aggregation switch and all the uplinks from the other run to the second aggregation switch. Here it is important to turn on Layer 2 trunk failover as discussed above. In this design, STP is not needed, and FlexLinks does not apply since there is no alternate path for either switch to forward traffic.

One disadvantage is the fact, that in the standalone operation, the servers can not form Active-Active NIC teams since each NIC is attached to a different switch.

Multiple pairs of switches per Blade Enclosure

Nothing in this design guide limits the user to a pair of Blade switches per enclosure. Some users may require more than two NICs per Blade. VMware typically wants four or six interfaces. By place two or three pairs of switches per enclosure, the server capacity can be increased. However, the number of enclosures grouped together by the VBS is reduced. At no time, can the limit of 9 switches per VBS be exceeded. Also, increasing the number of NICs per server may increase the traffic on the Ring. In the next section, the throughput of the ring will be discussed.

Configuration Steps

Configuring the Aggregate Switches

Complete the following steps on the aggregate switches:

- Step 1. VLAN configuration
- Step 2. RPVST+ configuration
- Step 3. Primary and secondary root configuration
- Step 4. Configuration of port channels between aggregate switches
- Step 5. Configuration of port channels between aggregate switches and Cisco Catalyst Blade Switch 3130s
- Step 6. Trunking of port channels between aggregate switches
- Step 7. Configuration of default gateway for each VLAN

Note: The "Configuration Details" section describes each of these steps.

Configuring the Cisco Catalyst Blade Switch 3130s

Complete the following steps on the Cisco Catalyst Blade Switch 3130s:

- Step 1. VLAN configuration
- Step 2. RPVST+ configuration
- Step 3. Configuration of port channels between the Cisco Catalyst Blade Switch 3130 and aggregate switches
- Step 4. Trunking of port channels between the Cisco Catalyst Blade Switch 3130 and aggregate switches
- Step 5. Configuration of server ports on the Cisco Catalyst Blade Switch 3130

Additional Aggregation Switch Configuration

The following recommendations help integrate the Cisco Catalyst Blade Switch 3130s into the data center.

- Step 1. Enable Root Guard on the aggregate switches' links connected to the switches in the blade enclosure.

The spanning tree topology is calculated and one of the primary parameters involved in this equation is the location of the root switch. Determining the position of the root switch in the network allows the network administrator to create an optimized forwarding path for traffic. Root Guard is a feature designed to control the location of the root switch.

The aggregation switches should employ the **spanning-tree guard root** command on the port channel interfaces connected to the blade switches.

- Step 2. Allow only those VLANs that are necessary on the port channel between the aggregate and the blade switches.

Use the **switchport trunk allowed vlan** *vlanID* command to configure the port channel interfaces of the aggregate switch to allow only those VLANs indicated with the *vlanID* option.

Additional Cisco Catalyst Blade Switch 3130 Configuration

- Step 1. Enable BPDU Guard on the internal server ports of the switch.

Use the **spanning-tree bpduguard enable** command to shut down a port that receives a BPDU when it should not be participating in the spanning tree.

- Step 2. Allow only those VLANs that are necessary on the port channels between the aggregate and the blade switches.

Use the **switchport trunk allowed vlan** *vlanID* command to configure the port channel interfaces of the switch to allow only those VLANs indicated with the *vlanID* option.

The following convergence tests were conducted against this alternative topology:

- Uplink failure and recovery between Switch-A and the primary root
- Uplink failure and recovery between Switch-B and the secondary root
- Failure and recovery of Switch-A and Switch B
- Failure and recovery of the primary and secondary root switches

These tests yielded results similar to the recommended topology. Layer 2 convergence occurs in approximately 1 second. As stated previously, recovery at Layer 3 is dependent on the HSRP settings of the aggregate switches (see “Recommended Topology” section). In our testbed, the failure of the active HSRP device typically increased the convergence time to 5 seconds.

This design supports traffic monitoring using SPAN and/or RSPAN. For example, a network analysis device connected to the external ports on the front of the Cisco Catalyst Blade Switch 3130 may capture locally mirrored traffic. Alternatively, RSPAN traffic may be carried on the Cisco Catalyst Blade Switch 3130 uplinks if bandwidth utilization is not a concern. For the steps to configure traffic monitoring, refer to the “Configuration Details” section.

Configuring the Aggregate Switches

Complete the following steps on the aggregate switches:

- Step 1. VLAN configuration
- Step 2. RPVST+ configuration
- Step 3. Primary and secondary root configuration

- Step 4. Configuration of port channels between aggregate switches
- Step 5. Configuration of port channels between aggregate and Cisco Catalyst Blade Switch 3130s
- Step 6. Trunking of port channels between aggregate switches
- Step 7. Configuration of default gateway for each VLAN

Configuring the Cisco Catalyst Blade Switch 3130s

Complete the following steps on the Cisco Catalyst Blade Switch 3130s:

- Step 1. VLAN configuration
- Step 2. RPVST+ configuration
- Step 3. Configuration of port channels between the Cisco Catalyst Blade Switch 3130s and aggregate switches
- Step 4. Trunking of port channels between the Cisco Catalyst Blade Switch 3130 and aggregate switches
- Step 5. Configuration of server ports on the Cisco Catalyst Blade Switch 3130

Configuration Details

This section describes the configuration steps required for implementing the topologies discussed in this guide. The configuration for the following are discussed:

- VLAN
- RPVST+ or FlexLink
- Inter-Switch Link
- Server Port
- Server Default Gateway
- RSPAN

VLAN Configuration

To configure the VLANs on the switches, complete the following tasks:

Set the VLAN trunking-protocol administrative domain name and mode and create the server farm VLANs as follows:

```
(config)# vtp domain <domain name>
(config)# vtp mode transparent
(config)# vlan 60
(config-vlan)# name bladeservers
(config-vlan)# state active
```

RPVST+ Configuration

Configure Spanning Tree Protocol to manage the physical loops in the topology. It is recommended to use RPVST+ for its fast convergence characteristics. Set the Spanning Tree Protocol mode on each aggregation switch as follows:

```
(config)# spanning-tree mode rapid-pvst
```

Configure the path cost to use 32 bits in the Spanning Tree Protocol calculations:

```
(config)# spanning-tree pathcost method long
```

Configure the primary and secondary root switches as follows:

```
(config)# spanning-tree vlan <vlan range> root primary | secondary
```

FlexLinks Configuration

Alternative to RPVST+, is FlexLinks. To enable FlexLinks, use the following commands:

```
(config)# interface tengigethernet1/0/1
(config-int)# switchport backup interface tengigethernet2/0/2
```

By doing this, the interface on member switch two will become the back up to the 10GE interface on member switch one. There are additional settings, including ones for the MAC Address Move function, including in the Software Configuration Guide for the particular switch model you are using. Please refer to those instructions for more details.

Inter-Switch Link Configuration

The topologies discussed in this guide require connectivity between the switches. The following two types of interswitch connections exist:

- Aggregate-1 to Aggregate-2
- Aggregate-1 or Aggregate-2 to Blade Switch-A or Blade Switch-B

Each of these connections may be a Layer 2 EtherChannel connection consisting of multiple physical interfaces bound together as a channel group or port channel. These point-to-point links between the switches should carry more than one VLAN; therefore, each is a trunk.

Port Channel Configuration

Link Aggregate Control Protocol (LACP) is the IEEE standard for creating and managing EtherChannel connections between switches. Each aggregate switch uses this feature to create a port channel across the line cards. The use of multiple line cards within a single switch reduces the possibility of the point-to-point port channel becoming a single point of failure in the network.

Configure the active LACP members on Aggregate-1 to Cisco Catalyst Blade Switch 3130 Switch-A as follows:

```
(config)# interface TenGigabitEthernet1/0/1
(config-if)# description <<*** Connected to Switch-A ***>>
(config-if)# channel-protocol lacp
(config-if)# channel-group 1 mode active
(config)# interface TenGigabitEthernet2/0/1
(config-if)# description <<*** Connected to Switch-A ***>>
(config-if)# channel-protocol lacp
(config-if)# channel-group 1 mode active
```

Trunking Configuration

Use the following guidelines when configuring trunks:

- Allow only those that are necessary on the trunk
- Use 802.1q trunking
- Tag all VLANs over a trunk from the aggregation switches

Configure trunks using the standard encapsulation method 802.1q as follows:

```
(config-if)# switchport trunk encapsulation dot1q
```

Define the VLANs permitted on a trunk as follows:

```
(config-if)# switchport trunk allowed vlan <VLAN IDs>
```

Modify the VLANs allowed on a trunk using one of the following commands:

```
(config-if)# switchport trunk allowed vlan add <VLAN IDs>
```

```
(config-if)# switchport trunk allowed vlan remove <VLAN IDs>
```

Define a port as a trunk port as follows:

```
(config-if)# switchport mode trunk
```

Note: The autonegotiation of a trunk requires that the ports be in the same VLAN Trunking Protocol (VTP) domain and be able to pass Dynamic Trunking Protocol (DTP) frames.

To secure and enforce a spanning tree topology, configure the root guard feature on the aggregate switch interfaces that connect to the blade switches. The following is an example of the interface configuration between the aggregate and blade switch with root guard enabled:

```
(config)# interface GigabitEthernet12/13
(config-if)# description <text>
(config-if)# no ip address
(config-if)# switchport
(config-if)# switchport trunk encapsulation dot1q
(config-if)# switchport trunk native vlan <vlan id>
(config-if)# switchport trunk allowed vlan <vlan id>
(config-if)# switchport mode trunk
(config-if)# spanning-tree guard root
(config-if)# channel-protocol lacp
(config-if)# channel-group <group id> mode active
```

The server ports on the blade switch support a single VLAN access and trunk configuration modes. The operational mode chosen should support the server's NIC configuration (that is, a trunking NIC is attached to a trunking switch port). Enable PortFast for the edge devices.

The BPDU Guard feature disables a port that receives a BPDU. This feature protects the Spanning Tree Protocol topology by preventing the blade server from receiving BPDUs. A port disabled with the BPDU Guard feature must be recovered by an administrator manually. Enable the BPDU Guard feature on all server ports that should not be receiving BPDUs.

Port Security limits the number of MAC addresses permitted to access the blade switch port. Configure the maximum number of MAC addresses expected on the port.

Note: The NIC teaming driver configuration (that is, the use of a virtual MAC address) must be considered when configuring Port Security.

```
interface GigabitEthernet1/0/1
description <*& BladeServer-1 *&>
switchport trunk encapsulation dot1q
switchport trunk allowed vlan 10, 60
switchport mode trunk
switchport port-security aging time 20
switchport port-security maximum 1 vlan 10, 60
```

```

no cdp enable
spanning-tree portfast trunk
spanning-tree bpduguard enable
end

```

Server Default Gateway Configuration

The default gateway for a server is a Layer 3 device located in the aggregation layer of the data center. This device may be a firewall, a load balancer, or a router. Using protocols such as HSRP protects the gateway from being a single point of failure and creates a highly available data center network. HSRP allows the two aggregate switches to act as a single virtual router by sharing a common MAC and IP address between them. Define a switched virtual interface (SVI) on each aggregate switch and use the HSRP address as the default gateway of the server farm.

Configure Aggregation-1 as the active HSRP router. The priority command helps to select this router as the active router because it has a greater value.

```

interface Vlan10
description <<** BladeServerFarm - Active **>>
ip address 10.10.10.2 255.255.255.0
no ip redirects
no ip proxy-arp
arp timeout 200
standby 1 ip 10.10.10.1
standby 1 timers 1 3
standby 1 priority 51
standby 1 preempt delay minimum 60
standby 1 authentication <password>
end

```

Configure Aggregation-2 as the standby HSRP router as follows:

```

interface Vlan10
description <<** BladeServerFarm - Standby **>>
ip address 10.10.10.3 255.255.255.0
no ip redirects
no ip proxy-arp
arp timeout 200
standby 1 ip 10.10.10.1
standby 1 timers 1 3
standby 1 priority 50
standby 1 preempt delay minimum 60
standby 1 authentication <password>
end

```

RSPAN Configuration

RSPAN allows for remote traffic monitoring in the data center. Define source and destination sessions to mirror interesting traffic to a remote VLAN captured by network analysis tools. Configure a VLAN for RSPAN on the Cisco Catalyst Blade Switch 3130 and the aggregate switch as follows:

```
(config)# vlan <vlanID>
(config-vlan)# name <vlan name>
(config-vlan)# remote-span
```

Create a source session as follows. This is the interface or VLAN that contains interesting traffic.

```
(config) # monitor session <session id> source vlan <VLAN IDs>
```

Configure the RSPAN VLAN as the target for the mirrored traffic as follows:

```
(config) # monitor session <ID> destination remote vlan <remote vlan ID>
```
